

A Web of Things Framework for RESTful Applications and Its Experimentation in a Smart City

Federica Paganelli, *Member, IEEE*, Stefano Turchi, and Dino Giuli, *Senior Member, IEEE*

Abstract—The Web of Things is an active research field which aims at promoting the easy access and handling of smart things' digital representations through the adoption of Web standards and technologies. While huge research and development efforts have been spent on lower level networks and software technologies, it has been recognized that little experience exists instead in modeling and building applications for the Web of Things. Although several works have proposed Representational State Transfer (REST) inspired approaches for the Web of Things, a main limitation is that poor support is provided to web developers for speeding up the development of Web of Things applications while taking full advantage of REST benefits. In this paper, we propose a framework which supports developers in modeling smart things as web resources, exposing them through RESTful Application Programming Interfaces (APIs) and developing applications on top of them. The framework consists of a Web Resource information model, a middleware, and tools for developing and publishing smart things' digital representations on the Web. We discuss the framework compliance with REST guidelines and its major implementation choices. Finally, we report on our test activities carried out within the SmartSantander European Project to evaluate the use and proficiency of our framework in a smart city scenario.

Index Terms—Internet of things (IoT), representational state transfer (REST), sensors, smart city, smart things, web, web of things, web services.

I. INTRODUCTION

THE WEB OF Things is an active research area that focuses on the specific challenge of making smart things accessible and manageable through open Web standards. This vision is correlated with the broader Internet of Things (IoT) research area aiming at enabling communication with and among smart objects, leveraging Internet standards and technologies [1].

As argued by the European Expert Group on Services in the Future Internet [2], huge research and development efforts have focused on lower level networks and software technologies, while “there is currently little experience with building applications for this new, emerging ecosystem of IP-enabled devices and objects.” As the Web facilitated both application

development and use for the traditional Internet, it is now expected to “unleash the potential of the IoT by making it accessible and programmable by developers who are not necessarily experts in ubiquitous computing” [2].

The Web of Things is expected to ease the access to smart things' capabilities and promote novel value-added services based on the combination of traditional web resources with those representing entities from the physical world (smart things, sensors, appliances, etc.) [3]. This has the big advantage of allowing the integration of smart things with the impressive amount of information resources and services already on the Web, as well as exploiting available technologies and best practices for web resource publishing and management.

On this perspective, the Representational State Transfer (REST) architectural style, developed as an abstract model of the Web architecture [4] is considered a reference paradigm for bringing sensors, and more generally smart things, into the Web [5]–[7]. Indeed, REST defines a set of principles for designing distributed hypermedia application fulfilling scalability, simplicity, and loosely coupling requirements.

Several research works have proposed approaches for implementing the Web of Things through REST principles, as discussed in the survey by Zeng *et al.* [8]. However, the path to the effective realization of the Web of Things is made difficult by the widespread misunderstanding of REST basics [9] and, consequently, the lack of software development frameworks that comprehensively support them [10], [11].

As a consequence, a main limitation of related work is that poor support is provided to web developers for speeding up the development of web applications for accessing, modifying, and composing information resources in the Web of Things domain [2] while taking full advantage of REST benefits.

In this paper, we propose an approach toward the Web of Things based on a graph representation of web resources, which can be accessed and modified at the desired and meaningful level of granularity through a REST-compliant uniform interface. According to our approach, a smart thing can be modeled as a graph of individually addressable web resources whose edges represent simple structural aggregation (i.e., containment) and reference relations. Graph-based representation of smart things can be interlinked with other types of information nodes to build a growing graph of globally addressable information resources that can be navigated, queried, and composed through a uniform REST interface.

The proposed framework consists of the following: 1) a Web Resource information model for representing smart things as web-accessible resources; 2) a middleware for handling and exposing these resources through a uniform API; and 3) a set

Manuscript received March 24, 2014; revised July 26, 2014; accepted August 28, 2014. Date of publication September 22, 2014; date of current version November 22, 2016. This work was supported in part by the European Commission through the SmartSantander Seventh Framework Programme-Information and Communication Technologies project.

of tools for easing the creation and handling of Web Resources as well as their web-oriented programming and publishing.

By leveraging the presented Web Resource model, middleware and tools users can easily create and modify digital representations of smart things, interconnect them with simple links, and publish them on the Web as RESTful resources.

Finally, we report on the use of the framework in a Smart City scenario within the SmartSantander European Project. The experiment consisted in the development of a web application for accessing sensors deployed in the city of Santander, Spain, as well as creating new virtual sensors. We also evaluated the end-user acceptance of the provided tools.

The remainder of this paper is organized as follows. In Section II, we present related work and motivate our contribution. Section III introduces the main principles of our approach and describes our framework. In Section IV, we describe the experiment carried out within the SmartSantander European Project to evaluate the proposed approach. Section V concludes this paper with insights on future work.

II. RELATED WORK

In this section, we briefly introduce the main principles of the REST architectural style. Then, to motivate our work, we analyze state-of-the-art solutions for middleware and application frameworks for the Web of Things.

A. REST Architectural Style

REST was proposed by Fielding [12] in his doctoral dissertation as an architectural style for building large-scale distributed hypermedia systems. By the REST vision, data sets and objects handled by client-server application logic are modeled as resources. REST key principles are fivefold [12].

- 1) *URIs as resource identifiers*. Resources are exposed by servers through URIs. Since URIs belong to a global addressing space, resources identified with URIs have a global scope.
- 2) *Uniform interface*. The interaction with the resource is fully expressed with four primitives, i.e., create, read, update, and delete. These operations can be mapped onto HTTP methods: GET reads the resource state, PUT updates the resource state, DELETE deletes a resource, and POST extends a resource by creating a child resource.
- 3) *Self-descriptive messages*. Each message contains the information required for its management.
- 4) *Stateless interactions*. Each request from client to server must contain the information required to fully understand it and is independent of any previous request.
- 5) *Hypermedia As the Engine Of Application State (HATEOAS)*. A hypermedia system is characterized by participants transferring resource representations that contain links; the client can progress to the next step in the interaction by choosing one of these links [13].

Historically, two styles opposed in the Web services field: Service-Oriented Architecture (SOA) and Resource-Oriented Architecture (ROA), i.e., WS-* and REST. Pautasso *et al.* [14] compare RESTful and WSDL/SOAP-based Web services, using architectural principles and decisions. The authors

conclude that RESTful services are more suited for tactical *ad hoc* integration over the Web (*à la Mashup*). Adamczyk *et al.* [11] evaluated some key questions regarding the real and perceived distinctions between the two styles and carried out a thorough analysis of Web services exposed by four repositories: 1) xmethods.net; 2) webservicex.net; 3) webservicelist.com; and 4) programmableweb.com reporting a very fast-paced growth of REST popularity. Moreover, in a study led in 2012 by Guinard *et al.* [7] involving 69 novice developers in implementing IoT client applications exploiting WS-* and REST approaches, results reported that REST is statistically significantly easier and faster to learn than WS-*. In addition, a considerable number of volunteers agreed that REST was more suited for Web applications requiring to integrate Web content: “[for] Web Mashups, REST services compose easily.”

Although RESTful APIs are deemed to be relatively simple, developing RESTful systems is difficult, and existing frameworks fail to support developers in conforming to REST constraints [10], [11]. The analysis provided by Zuzak and Shreier [10] highlights some weaknesses of existing general-purpose REST frameworks, such as the lack of structural and behavioral models for resource types, poor support of flexible mapping between resource representations and stored data entities, and the lack of support for scripting functions for read-write access to the application state at the client side. Adamczyk *et al.* [11] argue that current frameworks do not support well the “hypermedia constraint” or HATEOAS principle, and most of them do not fully support HTTP caching.

B. Middleware and Frameworks for the Web of Things

Zeng *et al.* provide a survey on research works in the WoT domain [8], where they highlight two main analysis criteria: the approach for integrating the physical things to the Web (i.e., direct and indirect integration) and the provision of composable services for enabling physical-virtual mashups.

Guinard *et al.* [15] provide a pioneering work contribution by specifying and implementing a set of REST services that expose functionalities of sensor nodes as web resources and link them together hierarchically. In a later work, this approach is applied in the AutoWoT project [16], a toolkit that facilitates the rapid integration of smart devices into the Web by offering a general way of modeling web resources and a mechanism for building web server components that expose the functionality of these devices. If the user modifies the Web resource at a later time, AutoWoT can semiautomatically regenerate the software for the Web exposure of the device.

Also, other works adopted the REST principles for implementing WoT-oriented systems. WebPlug [17] is a framework for the Web of Things that allows users to manage web resources representing sensors’ data and compose personal services based on physical objects. The representation of a web resource is enhanced using MetaURLs, i.e., textual labels that can be appended to the URL of the base resource to access some related information (e.g., collection of historic values).

Christophe *et al.* [18] present a prototype framework allowing the creation and handling of virtual objects. To validate their framework, they also introduce a web application that

allows end users to access the virtual objects and compose them according to basic event-based rules.

Uberdust [19] is a service-oriented platform that provides storage, sharing, and discovery of real-time and historical data from smart objects and sensor networks through the Web. These data can be accessed using REST and WebSocket APIs.

Significant efforts are ongoing to develop a Semantic Sensor Web [20] and integrate it with the growing body of knowledge available as Linked Open Data [21].

SemSense [22] is a system that collects data from physical sensors and publishes these data enriched with semantic annotations on the Web. SPITFIRE [23] is a service infrastructure that offers the semiautomatic generation of semantic sensor descriptions and efficient search for sensors and things based on their current states. Applications can issue search requests to SPITFIRE and then invoke retrieved services, directly.

C. Motivation of Our Work

While most works focusing on semantic descriptions of smart things [20], [22], [23] aim at providing efficient search and discovery capabilities, the scope of our work is to provide users with tools for accessing and programming the Web of Things, in compliance with REST guidelines.

Towards this objective, some previously mentioned works [16]–[19] provide tools for speeding up the exposure of REST APIs for accessing smart thing capabilities.

The original contribution of our work with respect to the ones mentioned earlier [17]–[19] is twofold: 1) the proposal of an information model representing web resources and their mutual relations and 2) the provision of tools supporting users in composing, publishing, and sharing the web representation of smart devices, which can be accessed through common web browsers. In the context of this study, we consider two different target users: 1) developers of the WoT (*developers* from now on) and 2) tech-savvy users with rudiments of web technologies (*users* from now on). In Section III-C, we will discuss tools created for both categories. Finally, the term *end user* will refer to people without particular domain competences, e.g., ordinary “Web surfers.”

Our work shows more similarities with AutoWoT [16] since both adopt a Web Resource model and provide services supporting the exposure of smart devices as web resources. However, a significant difference exists in the modeling approach. The AutoWoT resource model relies solely on a hierarchical relation among resources; consequently, a physical thing is represented as a hierarchical collection of web resources. We argue that a mere hierarchical relation is not fully compliant with the REST hypermedia constraint (i.e., reference links among resources drive the application state evolution and shall be advertised by the server at each interaction step). Since, as argued by Vinoski, “relationships between resources and how the server makes those relationships available to applications are at least as important to REST developers as resource naming,” our approach relies on a graph-based model that includes two main types of relations among web resources (i.e., aggregation and reference). Purposely, these relations recall how, in fact, web resources are organized and can be navigated in traditional

web sites. In addition, InterDataNet (IDN) is natively capable of handling sets of resources, and this has the following implications: 1) using the Web Resource REST resource exposed by the middleware it is possible to perform aggregated operations on graphs, e.g. to retrieve, create or update more vertexes at the same time; and 2) the Web Resource model describes sets of Nodes (at the limit, made of one element only) and is particularly suited for hosting properties which are strongly affected by information aggregation practices, such as privacy. Moreover, unlike AutoWoT, the IDN model offers a scriptable Node, called Activity Node (see Section III-A), which is able to perform processing operations on other Nodes’ contents and output the computation result. This scenario seems to be very promising for device virtualization. Leveraging this model, we propose a set of capabilities supporting developers and users in representing smart things as Web Resources and composing them with existing web resources, to build novel applications.

III. WEB OF THINGS RESTFUL FRAMEWORK

Our work aims at leveraging Web principles for making a Web of Things easy to access and program. Our framework provides tools for easing both exposure and handling of smart devices (and related information) as web resources. These web resources can be composed with “traditional” ones to facilitate the creation of web applications and services. This objective requires a dedicated adaptation layer mediating the interaction with sensor and actuator implementation technologies that have not been designed with the Web exposure requirement in mind.

It is widely accepted that REST is the architectural style for the Web, and our approach for web resource exposure is based on its principles. Since the mere adoption of mainstream REST frameworks does not guarantee the compliance with all REST guidelines [10], [11], our work aims at helping developers in taking such constraints into account. More specifically, our framework provides support to the following.

- 1) *Resource type definition and design.* We propose a graph-based information model for representing web resources, called Web Resource model.
- 2) *General-purpose software for exposing and handling operations on web resources.* Our system includes a set of middleware services for exposing web resources through a REST uniform interface.
- 3) *Mapping between web resource representation and legacy data sources.* The middleware is based on a layered architecture that distinguishes the web exposure layer (dealing with web resource model and representation, content negotiation, and RESTful uniform interface exposure) and the layer dealing with storage of data entities and/or the retrieval from external sources.
- 4) *Programming and Web Publishing tools.* These consist of Java and JavaScript libraries for easing the development of web applications for the Web of Things, a web application allowing users to graphically access, modify, and create new web resources according to our model, and a plugin for their rendering and visualization in ordinary web browsers.

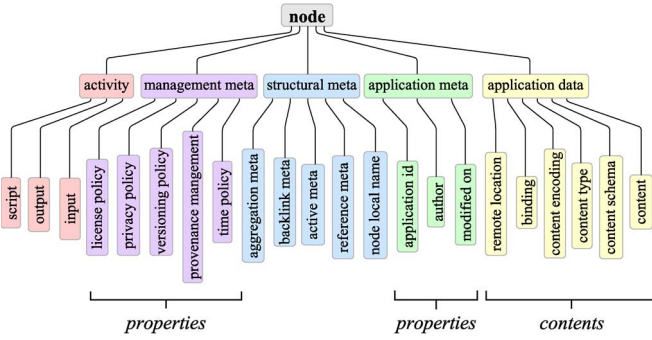

Fig. 1. First level element hierarchy of the Node data model. Vertical texts specify whether these elements are used to implement contents or properties.

As detailed in Section III-A2, our information model represents web resources as nodes (containing data and metadata) interconnected through links, to create a browsable graph of information. Our model has two types of structural links: aggregation (i.e., containment) and reference relations. Leveraging the modeling capabilities and programming tools made available by our framework, a smart thing is modeled as a graph of individually addressable web resources handled through a REST interface, at the desired level of granularity. This graph-based representation allows to easily represent smart things as sets of nodes that can be interlinked and connected with other resources (e.g., information resources of the “traditional” Web of Documents) to build a growing graph of globally addressable information that can be navigated, queried, reused, and composed through a uniform REST interface. Hereinafter, we will consider sensors as smart thing reference examples.

A. Web Resource Model

In the following, a few definitions are given before introducing the Web Resource concept.

Definition 1: A **Node** is a tuple $N = (C, P)$, where C is the set of content elements (i.e., data) and P is the set of properties (i.e., metadata) that characterize the content. A nice URI [12] associated to every node is used as a unique identifier.

Definition 2: An **Aggregation link** is a directed link between two Nodes that represents a container-content relation. The conveyed meaning is the following: The originating node aggregates, and therefore contains, the destination node.

Aggregation is a transitive relation: Given two nodes n_0 and n_1 connected via an Aggregation link departing from n_0 and pointing to n_1 ($n_0 \rightarrow n_1$), we are implicitly stating that n_0 contains n_1 . As a consequence, given a third node n_2 so that $n_1 \rightarrow n_2$, we can say that n_0 contains n_2 .

Definition 3: A **Reference link** is a directed link between two Nodes that represents a pointer toward a referred resource (i.e., the destination node). No further meanings are associated with Reference links. To better understand the Reference link role, it could be somehow compared with the HTML href attribute.

1) **Node Data Model:** The Node data model is made of four elements, as shown in Fig. 1: ApplicationData, ApplicationMetadata, StructuralMetadata, and ManagementMetadata.

The ApplicationData is the section entitled to host contents, i.e., the information to be consumed or produced by applications. This section includes Content, ContentSchema, ContentEncoding, and ContentType subsections which wrap the content itself, the location hosting the related content schema (if available), the encoding algorithm (e.g., base64), and the content type expressed in multipurpose internet mail extensions type notation [24], respectively. These subsections are crucial for supporting content reuse. Indeed, our paradigm is conceived to encourage information reuse, and when a client (e.g., an application) retrieves a Web Resource, it should be able to handle its contents by choosing proper decoding and parsing algorithms.

The information contained in the ApplicationMetadata section can be used for tracing applications’ modifications. When a client modifies a Web Resource, the Information History module (see Section III-B) runs a versioning procedure to persist that Web Resource latest version. These metadata provide information about the author of the modification such as the related time stamp, the identifier of the application responsible for the creation, and the author of the resource.

The StructuralMetadata section contains references to Link elements originating from the Node, and because of this, it takes part in the graph’s structure. For every link type, additional information is provided such as a local name, description metadata, allowed operations to support the HATEOAS paradigm, and, of course, the referred URI.

The ManagementMetadata section may contain properties that further characterize the Node in terms of licensing, privacy, provenance, time, and versioning. More specifically, the LicensePolicy element may be used to declare the licensing policy in force for the Node. The PrivacyPolicy element basically states whether the Node contains identifying and sensitive information. The ProvenanceManagement element contains information concerning the enforced provenance strategy [25], [26]. The TimePolicy element specifies whether the node should be destroyed or invalidated after (or before) a certain date. Finally, VersioningPolicy specifies which versioning policy should be applied to the Node.

The Activity section is dedicated to the specification of a script for dynamically generating contents. A scripted Node is called Activity Node and presents special outgoing edges (Active Links) defining dependences pointing to Nodes containing inputs required for the script computation. When a request is issued for an Activity Node, its dependences are resolved before executing the script. The output of the script constitutes the content information for the current Node to be included in the ApplicationData section. In the authors’ experience, Activity Nodes are very handy to represent Web Resources whose content depends on contents of other Web Resources. A significant example is the Virtual Sensor, which is a nonphysical sensor whose output is a function of other feeding sensors’ outputs. This is particularly useful to increase the coverage of existing sensors or to define derived measurements, such as the Heat Index [27] which combines temperature and humidity.

2) **Web Resource Exposure:** The **Web Resource** is the REST resource exposed by the IDN and is defined as a directed graph $R(N, L_{Aggr})$, where N is the set of Nodes (with $|N| \geq 1$)

TABLE I
WEB RESOURCE URI SYNTAX

Fragment	Regex	Semantics
node_name	<code>[^\[][/\w]*[^\[]</code>	The name of the Node.
inner_path	<code>[^\[][/\w]*[^\[]</code> , iff the character sequence identifies a valid node's section.	The name of the inner section of the Node.
content_path	a valid (reduced) XPath expression	The specification to reach parts of structured contents.
version	<code>[^\.][\d]*[^\.]</code>	The version of the Node.
res_depth	<code>[^\d]</code>	The number of edges to explore starting from the Root Node, determining the retrieved Nodes.

and L_{Aggr} is the set of Aggregation Links. A Web Resource has a single Root Node n_R , i.e., a Node with no incoming Aggregation Links. A Web Resource representation can contain a different number of Nodes, determined by dedicated URI parameters. Nodes are served by resolution levels, taking as reference the geodesic distance [28] from n_R .

A URI for a Web Resource has the following syntax:

`http://auth/node_name/$inner_path/- $content_path/
$version/$res_depth?keys=vals.`

The `auth` fragment defines the authority as defined in the URI specifications [29], `node_name` is a path determining the name of the current Node, `inner_path` is an optional filter selector specifying which part of the Node is required (e.g., the `ApplicationData` or `StructuralMetadata` explained in Section III-A1), `content_path` is an optional XPath [30] expression targeting specific elements in structured contents, `version` is an optional parameter specifying which version of the Node is requested, and finally, `res_depth` is an optional parameter specifying the resolution depth as the number of hops from the current Node. The `content_path` parameter requires an additional explanation: A Node can contain either structured (e.g., XML or JSON) or unstructured (e.g., plain text) data. In the first case, is possible to exploit the underlying structure to offer additional filtering capabilities based on content elements (for example, if the Node contains a bookstore, it is possible to filter authors, provided that they are represented in the bookstore structure). Since it is not possible to make any assumption on the adopted content format, `content_path` must use a generic syntax. To this end, we used a reduced set of the XPath syntax excluding XML peculiarities (e.g., attributes and namespaces). Table I summarizes the fragments' meaning.

A Web Resource is exposed to external clients through a uniform CRUD interface, made of a fixed set of operations: create, read, update, and delete. These operations can be mapped onto HTTP methods: GET reads the resource state, PUT updates the resource state if the resource already exists and creates it if otherwise, and DELETE deletes a resource. In order to keep the interaction with resources flexible, easy, and comprehensive, much effort has been put in making it fully RESTful. Specifically, three aspects have to be highlighted: First, content negotiation is available for Nodes. The current implementation allows a client to request XML, JSON, and HTML representations. As explained in Section III-C4, HTML representations are produced by a JQuery plugin which requests

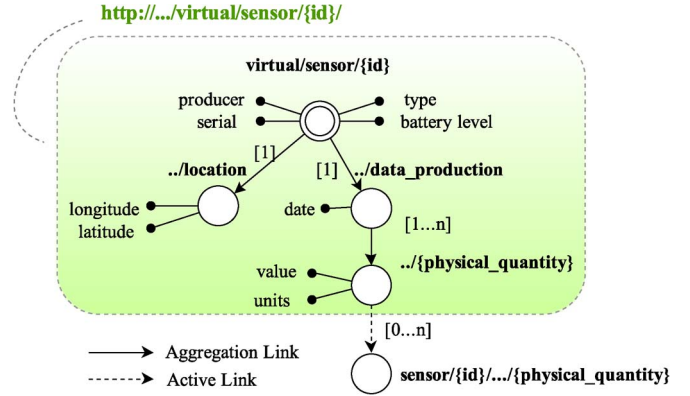

Fig. 2. Web Resource representing a generic sensor (Virtual Sensors have Active links to other sensors while normal sensors have not). Since the Web Resource is defined as a graph of Nodes, operations on sets of Nodes are enabled. In this regard, the boxed subgraph shows the Web Resource retrieved when a user requests a complete sensor resolution: Not only the sensor Node but also all its contents (i.e., all the aggregated Nodes) are returned. Please note that a complete resolution is triggered by issuing a GET request on the sensor's URI followed the ending "/" character.

(via AJAX) and processes a JSON representation, generating a human-oriented version of it. Such strategy is motivated by the fact that a set of Nodes could have a meaningful visual arrangement that disregards the strictness of the graph structure. This can be seen as an application of the code on demand style [12]. Second, in order to avoid conflicts while updating resources, ETags [31] are used to represent their status. Third, as stated earlier, HATEOAS [12] is supported by including in the Node representation links to the next related resources (whether Reference or Aggregation Links) as well as instructions on how to interact with them.

3) *Examples:* By the Web Resource model, a smart thing can be represented as a graph of structured information pieces.

Fig. 2 shows a simplified example of a sensor modeled as a graph of Nodes (depicted as circles). These Nodes contain the granular information (black pins) and are connected by arrows representing relations. The `sensor/{id}` labeled vertex carries the content describing the sensor's characteristics, i.e., descriptive information (producer and serial number), capabilities such as the type of sensor (e.g., temperature sensor), and dynamic information such as battery load percentage. This vertex has two children (`/location` and `/data_production`). The location Node is used to identify the sensor's geographical position in terms of longitude and latitude, while the subtree having `data_production` as root represents the sensor's observations. In particular, the `data_production` vertex contains information on the last measurement date time, and its direct children identified with `physical_quantity` (i.e., temperature, light, noise, and CO index) contain actual measurement values. Please note that common sensors and Virtual Sensors are represented by the same model, with minimal modification. In the case of a Virtual Sensor, the `physical_quantity` Node is an Activity Node, and edges to `physical_quantity` Nodes belonging to other sensors are Active Links.

Table II provides an example of the uniform interface constraint applied to the a sensor Node. The API semantics applies

TABLE II
IDN REST APIs FOR A SENSOR WEB RESOURCE

HTTP Verb	URI	Semantics
GET	.../sensor/{id}	To retrieve the single node identified by the URI.
GET	.../sensor/{id}/	To retrieve all the nodes aggregated by the node identified by the URI.
GET	.../sensor/{id}\$n	To retrieve all the aggregated nodes being distant n hops from the node identified by the URI.
PUT	.../sensor/{id}	To create the node identified by the URI, or modify it (if it already exists).
DELETE	.../sensor/{id}	To delete the node identified by the URI.

identically to every Node belonging to the sensor or virtual sensor Web Resource graph.

B. Middleware

The framework includes a middleware, called IDN, that offers capabilities for handling web resources compliant with our model (i.e., Web Resources; see Section III-A2), exposed through a RESTful uniform interface.

The core of the IDN middleware is the result of previous works [32], [33], and it was applied to the development of RESTful web services in different domains such as health care [34] and management of radio-frequency identification-related events [33].

For the purpose of this work, the middleware core has been extended in order to accomplish the following: 1) cope with external information sources (e.g., sensors, gateways, etc.) interoperability requirements and 2) improve both developer and user support in smart things' digital representation design and handling, through programming APIs or web browsers.

The IDN implementation adopts a modular pattern enforcing the separation of concerns principle. Core modules are Virtual Resource, Information History, and Storage Interface.

Virtual Resource is in charge of managing and exposing Web Resources. In fact, it exposes REST uniform APIs for accessing and managing smart things' web representations. These REST services can be accessed by end users through web browsers (enhanced with appropriate REST-enabling plugins) or by other web applications. As shown in Fig. 3, different Virtual Resource instances dialogue as peers to realize a distributed graph of interconnected Nodes. In this way, it is possible to reach Web Resources spanning different domains from a single access point.

Information History provides versioning capabilities for Nodes. This is useful for tracking the history of a resource, supporting cooperation by allowing branching and merging, and enforcing provenance by allowing a thorough inspection of previous states. This service is not mandatory and can be disabled according to specific application/publisher requirements.

Storage Interface provides data and metadata persistence capabilities. IDN-specific metadata (e.g., the ones described in Section III-A) are always persisted in the Storage Interface domain, while data can be either native or external. Native data are created directly in IDN and are managed by the

Fig. 3. Overall view of the IDN architecture.

Storage Interface persistence service. Conversely, external data are owned by other sources and are never replicated on the IDN side by default. In order to cope with external data, IDN stores their references (more precisely, IDN stores the references of interchange resources exposed by the Adapter which, in turn, keeps the mapping toward the external data source). External data require the Adapter mediation to be managed as native resources. Storing references is a good strategy to avoid bottlenecks while dealing with frequently changing data (e.g., sensors' outputs). IDN applies this strategy also to treat historical data, whether they are provided by an external data source or a custom *ad hoc* service.

Virtual Resource, Information History (which is in an ongoing stage of implementation), and Storage Interface have been developed as Java 7 Web Applications running on an Apache Tomcat Application Server. They have been implemented leveraging the Spring framework [35], Hibernate [36], JAXB [37], and JSP [38] technologies.

The core middleware includes also a Search Service, based on Apache Solr [39], offering search capabilities for retrieving indexed Web Resources. The Search Service exposes a REST-based search interface for submitting queries based on keywords, time, and/or location parameters. Semantic search and discovery is currently under development.

The Adapter is the component that support the interworking of the IDN middleware with external data sources. Thus, an adapter component contains *ad hoc* intermediation logic for exposing data and services provided by legacy systems and devices according to our graph-based Web Resource model. In this way, properties enabled by the IDN resource model can be applied to information originating from outer sources.

The Adapter is also designed with a modular approach and includes four components: 1) a Notification Manager which manages the Adapter subscription to the data source, enabling a push/pull notification service; 2) a Transformer module which refines data served by the outer source (e.g., demultiplexing the information to achieve a more granular representation); 3) a Web Resource Manager which assembles the outer information in a graph structure compliant with the Web Resource model;

and 4) a Translator which translates requests coming from the IDN Service Architecture interface in a communication format supported by the data source (e.g., a PUT request to the IDN Service Architecture could map to a POST request to the data source).

Basically, the Adapter is thought to be connected to services exposed on the Web such as WS-*, REST, RDF, and so on. However, there are no theoretical problems to connect it with different data sources. Indeed, the Adapter is an intrinsic customizable component, and different configurations can be supported by different Adapter instances. The Adapter can be semiautomatically configured in terms of communication interface toward the data source (e.g., by exploiting interface descriptions such as WSDL) and Web Resource modeling of external data (e.g., by exploiting relational database schemas to build the graph model).

C. Programming and Web Publishing Tools

To fully exploit the features provided by IDN, we also developed a set of tools for easing the use of the Web Resource model and REST APIs as well as the development of web applications on top of them. To this end, we provided four tools: 1) a Java library for server-side programming, called IDN Java Library; 2) IDN.js, a client-side JavaScript programming library; 3) a web application providing a graphical interface for designing and managing Web Resources, called IDN-Studio; and 4) IDN-Viewer, a highly customizable jQuery plugin that automatically renders HTML views from Web Resources returned by the IDN middleware.

While our Java and JavaScript libraries are thought for developers and provide APIs for easing the interaction with the middleware as well as Web Resource instance handling, IDN-Studio and IDN-Viewer are conceived to lower the effort required by users for creating, modifying, and publishing new resources to be shared with other users and end users.

1) *IDN Java Library*: The IDN-Java Library provides features for easing the server-side programming of web applications that handle Web Resources exposed by the IDN middleware. Its main components are the following:

- 1) `it.unifi.idn.webresource` package providing a java-based internal representation of the Web Resource model;
- 2) `it.unifi.idn.IdnElement` class that exposes methods for manipulating the Node;
- 3) an IDN client implementation in charge of interacting with the IDN middleware for performing CRUD operations on Web Resources.

2) *IDN JavaScript Library*: This library provides a set of functions for client-side programming easing the interaction with the middleware and the handling of the returned Web Resource representations.

The `it.unifi.IDNjs.Manager` class defined in this library handles the RESTful invocations to the IDN middleware to retrieve, delete, and write single-Node or multiple-Node Web Resources, while the `it.unifi.IDNjs.Node` class represents the Node and exposes methods for internally managing the content, links, and metadata. The offered APIs

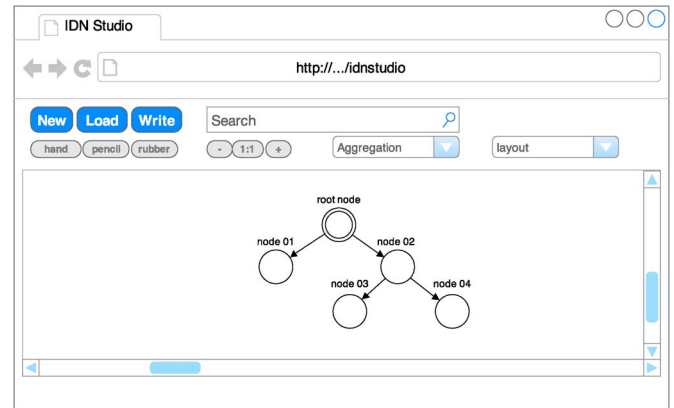

Fig. 4. Mock-up of the IDN-Studio application.

are not significantly different than the ones discussed for the Java Library and therefore will not be detailed here. The library has been implemented by leveraging JQuery [40] as a helper library, JSON-js [41] for (un)marshalling document resources, and an AJAX [42] client.

3) *IDN-Studio*: IDN-Studio is a JavaScript web application for the visual management of Web Resources, providing the user with a full control over the graph structure and data. IDN-Studio interacts with the middleware through the REST APIs exposed by the Virtual Resource and allows users to create new Web Resources and delete or modify existing Web Resources by adding or removing Nodes, contents, and properties. A search form is also available for querying the IDN Search Service in order to retrieve indexed Nodes.

Fig. 4 shows a mock-up of the IDN-Studio GUI that emphasizes the main operations available (e.g., a search form, buttons for reading, writing, and loading Web Resources, and editing tools displaced on the dashboard). A running instance is available at <http://idn.dinfo.unifi.it:20282/idnstudio>.

4) *IDN-Viewer*: While IDN-Studio provides a human-oriented representation of Web Resources conceived for easing their management, IDN-Viewer addresses the problem of their rendering on a web browser. Its main task consists in parsing the resources returned by the middleware and, depending on their structure, generating rich HTML web pages.

IDN-Viewer is able to choose the proper visualization for different types of content by inspecting the `ContentType` section of the `ApplicationData` and selecting the appropriate widget. For example, structured contents such as JSON or XML are rendered as tables, images (jpeg, png, etc.) are rendered as clickable thumbnails, and plain text is rendered as is.

More specifically, for each resource to be displayed, the plugin takes its URI as a key parameter and performs an AJAX request to retrieve it from the middleware. Then, the returned representation is parsed, and proper transformation rules are applied. Moving from the Root Node, an algorithm is run to analyze the graph of interlinked Nodes. Resources referred by Reference links are organized as menus. The algorithm interprets Aggregation relations differently, depending on the geodesic distance d_j , i.e., the length of a shortest path evaluated on Aggregation edges between the Root Node n_R and the Node n_j . We define a configurable threshold D . Nodes for which

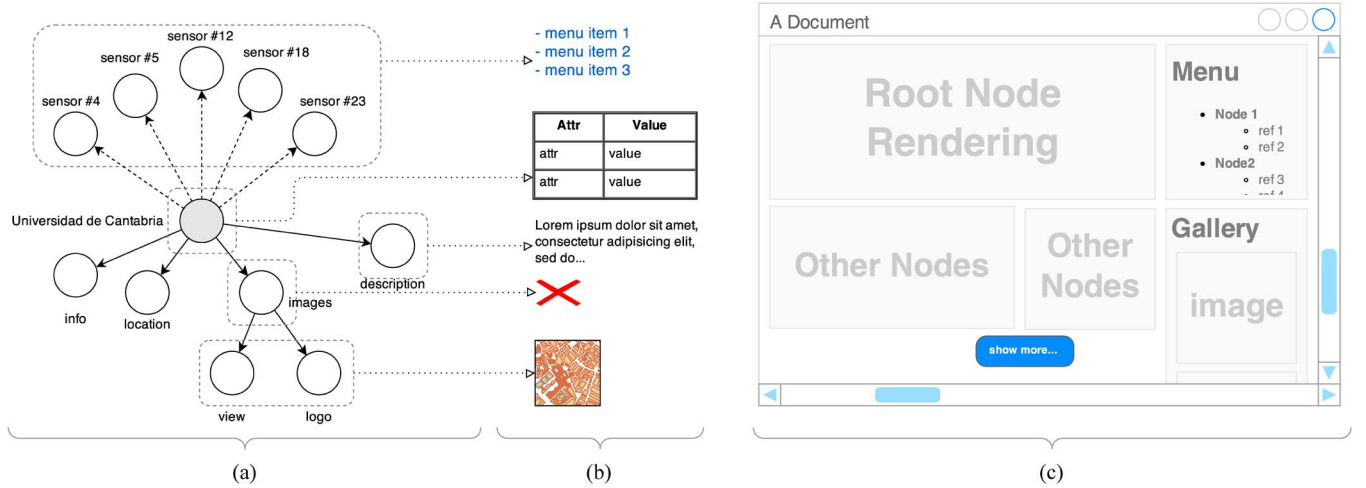

Fig. 5. Mapping rules in IDN-Viewer. (a) Web Resource representing the "Universidad de Cantabria" PoI, including descriptions, location-related data, and near sensors. (b) According to information formats, data are rendered as different types of widgets. (c) Contents are finally arranged in the canvas to meaningfully fit the available space.

$d_j < D$ are organized in container elements (e.g., `<div>` HTML elements) and shown on the canvas. If there exists at least one node n_j such that $d_j \geq D$, a "show more" button is included in the layout. As the button is pressed, a (configurable) amount of remaining Nodes are loaded and displayed on the canvas. This strategy helps in keeping the Web Resource's HTML representation clean, supporting human-friendly inspection by incrementally filling the canvas space.

IDN-Viewer has been implemented as a plugin for the popular JQuery [40] JavaScript framework. It is highly customizable and configurable and is not coupled with any cascading style sheets framework.

Fig. 5 shows the rationale behind the HTML rendering of a Web Resource representing the "Universidad de Cantabria" Point of Interest (PoI) [see Fig. 5(a)]. Nodes constituting the Web Resource are inspected to generate a widget that better presents their contents [see Fig. 5(b)]. Finally, elements and widgets are arranged on the canvas to produce a meaningful representation of the original Web Resource [see Fig. 5(c)].

IV. EVALUATION

In this section, we describe the experiment carried out in the context of the SmartSantander European Union (EU) Project. This experiment, previously introduced in [43], aimed at evaluating how our proposed approach supports developers and users in taking advantage of Web of Things resources and, more specifically, in designing and developing web applications that mediate the end-user interaction with these resources.

The main objective of the SmartSantander project [44], [45] was to create a primary European test facility for the research and experimentation of architectures, services, and applications for the IoT [45]. It consists of a real-world smart city deployment in Santander (Spain) that offers a large variety of sensors (e.g., temperature, CO, noise, light intensity, and parking occupancy). Owing to the SmartSantander facility, our experiment exploited real-world sensor data.

The experiment description is structured as follows. First, we introduce *MySmartCity*, a web application that we developed exploiting our Java and JavaScript libraries. It served as a demonstration of a rich web application that can be implemented by developers on top of our middleware. Second, we show how IDN-Studio and IDN-Viewer enable a user to create, handle, compose, and extend Web Resources that represent Santander's sensor facility. Then, we describe the testing activities aimed at evaluating the user acceptance of the implemented features. Finally, we report on further testing activities for evaluating the performance of IDN.

As an experiment prerequisite, we developed an Adapter for interacting with the push/pull HTTP-based APIs exposed by the Santander facility. The Adapter can execute an initialization routine that does the following: 1) queries Santander APIs for sensor-related information and parses it; 2) generates a graph of Nodes (i.e., a Web Resource) for each sensor; and 3) commits it to the middleware. These Nodes are stored in the system as metadata specifying their characteristics and relations along with a reference to the actual real-time measurement provided by Santander APIs. Once the initialization phase is over, sensors' data are exposed as a set of URI-addressable Nodes, accessible through REST APIs (called IDN Santander APIs). In the normal operating phase, the Adapter retrieves up-to-date measurement values from the Santander facility when required by the Virtual Resource/Storage Interface layer (upon a request). The Adapter also handles notifications sent by the Santander facility as some events of interest occur (e.g., a new measurement value and a new registered sensor).

A. *MySmartCity* Application

MySmartCity is a web application that allows end users to browse sensors, create new Virtual Sensors (such as an Heat Index sensor close to the end user's home), and store them in the system for later access. End users can also create Web Resources representing PoIs (such as the one introduced in Section III-C4) and enrich them with descriptive information

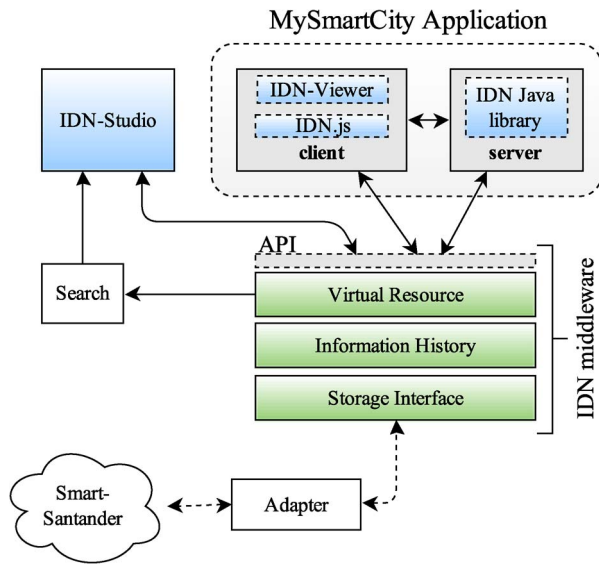

Fig. 6. Interaction of MySmartCity application with the middleware. All the framework components are visible: IDN middleware, Java and Javascript libraries, IDN-Viewer, and IDN-Studio. At the bottom is shown the Adapter component interfacing with the SmartSantander facility.

and references to sensors in geographical proximity. Eventually, they can also share them with other end users. A PoI can be public (a tourism location and a public transport station) or have meaning in a user's personal scope (e.g., user's home). Both Virtual Sensors and PoIs can be made public by the administrator, upon a request of the owner.

MySmartCity application logic runs both the client side and server side. Apart from application-specific details, MySmartCity contacts the IDN middleware to retrieve, update, and manage Web Resources whether they are Sensors, Virtual Sensors, or PoIs. To this end, the tools described in Section III-C proved to be quite handy. Indeed, the Java and JavaScript libraries have been used for programming the server and client, respectively, while IDN-Viewer has been used to display a human-oriented representation of PoIs, enriching significantly the user experience. In this context, IDN-Studio played also a very important role in redesigning and adjusting Web Resources, created through the application GUI. In fact, to modify the model used for a certain information object (e.g., a PoI), a user can load it in IDN-Studio and visually edit it. With a few clicks, modifications are committed to the architecture, and the object is redesigned. Fig. 6 provides a detailed outline of how the application interacts with the middleware. Programming and publishing tools are also represented.

B. User-Centric Creation of Web of Things Applications

MySmartCity application allows end users to create and share new web contents, in a smart city scenario. However, the type of information that they can add is predetermined by the developer who designed the Virtual Sensor and PoI information models and the related client- and server-side logic.

Hereinafter, we describe how IDN-Studio and IDN-Viewer tools enable a user-centric creation of a personal Web of Things application, by allowing end users to freely modify and handle

their custom Web Resources (i.e., Virtual Sensors, PoIs, and also new resources defined by the user), publish them on the Web, and access them through an ordinary web browser.

Through IDN-Studio, a user can access the model of a given Web Resource and browse the graph of Nodes by exploring Aggregation and Reference links. Leveraging the features provided by the tool, the user may modify the Web Resource's representation, for example, by editing the ApplicationData, creating new links or deleting existing ones. The process of user-centric creation of Web Resources for a personal Web of Things is completed when the "write" button in the dashboard is clicked. This action triggers a sequence of REST operations for committing the changes to the middleware (e.g., PUT for modifications to an existing resource).

For instance, a user might be interested in creating a PoI that aggregates some noise and parking sensors close to his home. He might also create another PoI at a different location (for instance, his relatives' home with surveillance and health sensors) and create a third Node that aggregates these two PoIs. The URI of this new Node can be seen as the root page of a personal web application created to easily access and monitor personal information. Indeed, the newly created and modified Web Resources are now accessible from standard web browsers and can be navigated as plain web pages that have been automatically generated by the IDN-Viewer plugin.

C. Evaluation With Users

We conducted testing activities focused on evaluating the user acceptance of implemented features. More specifically, our objective was threefold: 1) Evaluate the perceived ease of use and effectiveness of IDN-Studio and IDN-Viewer tools; 2) analyze potential disadvantages, and qualify them (e.g., major usability problems and technical bugs); and 3) gather subjective user satisfaction evaluation and possible suggestions for future improvements. Please note that Java and JavaScript libraries have not been tested in this session, so we are interested in the *user profile* (see Section II-C).

The evaluation session has been organized as a half-day workshop and was conducted with 20 users. Users were selected among our colleagues in the Department of Information Engineering at the University of Florence. The majority of them (80%) work in the field of Radar, Remote Sensing and Signal Processing fields and, to our purposes, can be considered average users, while a minority of them work in the fields of middleware and application protocols (10%) and are also expert web developers. None of them work in the field of IoT or WoT nor have previously used the tools under evaluation. All users are aged within 30–44 years.

In the first part of the workshop, a member of the experiment team presented the SmartSantander project, briefly introduced the tools to be evaluated, and explained the meaning of Virtual sensors and PoI resources.

In the second part of the workshop, the users were asked to use the MySmartCity application and IDN-Studio to customize an existing PoI through IDN-Studio (e.g., by enhancing its representation with a picture and historic information) and evaluate its rendering performed by IDN-Viewer.

TABLE III
EVALUATION RESULTS FOR IDN-STUDIO AND IDN-VIEWER

Question	Definitely Yes	Yes	Neutral	No	Definitely No
Was IDN-Studio intuitive and easy to use?	20%	20%	60%	0%	0%
Was it easy to modify a PoI through IDN-Studio?	0%	40%	60%	0%	0%
Did you succeed in designing the target PoI?	0%	60%	40%	0%	0%
Were you satisfied by the graphical rendering of your personalized PoI on the web browser?	20%	60%	20%	0%	0%
Was the content of the PoI organized as you expected?	0%	80%	20%	0%	0%

User feedbacks have been collected through interviews and a questionnaire at the end of the evaluation session. Table III shows feedbacks provided on the use of IDN-Studio for modifying and enriching the description of a PoI. Users succeeded in completing the assigned tasks, and 40% considered the application intuitive and easy to use. The majority of users provided positive comments on the visualization of the changes that they applied to the PoI on the web browser. Some suggestions were made to enhance the interface with help texts to guide a first-time user in the use of the tool.

Although these evaluation activities are preliminary, results are encouraging and provided useful suggestions for correcting our applications. Since assessing user acceptance is considered a key topic to be investigated toward the Future Internet [46], a more in-depth evaluation of factors relevant to user acceptance, such as those analyzed by Lizcano *et al.* [47], would be worthwhile in the near future involving a wider and more heterogeneous user group.

D. Performance Evaluation

We also carried out testing activities to analyze the performance of the IDN middleware implementation.

The test environment was deployed on two virtual machines, both equipped with 1-GB RAM and running the Debian 6 distribution. These Virtual Machines (VMs) were installed on an HP ProLiant ML350 server with two Intel Xeon quad-core processors, 17-GB RAM, and Debian 6 OS. One VM hosted the IDN Middleware, while the second VM hosted the MySmartCity and IDN-Studio applications.

The objective was to assess the time required by the following two main operations: 1) creation of a Web Resource (HTTP PUT request) 2) retrieval of a Web Resource (HTTP GET request). Each operation was performed on resources with varying size (i.e., composed by 1, 10, 30, and 50 Nodes) whose application content was stored in the IDN middleware (no requests to external information systems were required). We iterated each test ten times and measured the elapsing time from request delivery to response reception at the server side.

Table IV shows the truncated mean value of the obtained measurements. It is worth observing that the time required

TABLE IV
PERFORMANCE RESULTS FOR THE IDN MIDDLEWARE

Request Type	Web Resource size	Response Message Body (KB)	Request-response time (ms)
Creation	1 Node	0.722	192
	10 Nodes	5.6	2253
	30 Nodes	15.1	5606
	50 Nodes	25.2	10748
Retrieval	1 Node	0.772	73
	10 Nodes	5.6	625
	30 Nodes	15.1	1704
	50 Nodes	25.2	2865

for creating or retrieving a Web Resource grows linearly with the number of aggregated nodes. This behavior was expected since sets of Nodes belonging to the same Web Resource are managed sequentially by the middleware components in the current prototype implementation. Such behavior can be improved by implementing parallel processing tasks.

V. CONCLUSION

In this paper, we have proposed a framework for modeling and turning smart things into web-addressable resources that can be accessed and handled through a REST uniform interface. The framework is composed of a general-purpose model for web resources and a middleware that implements RESTful services for handling these resources through open Web standards.

The proposed model is based on two simple relations (Aggregation and Reference), chosen for their relevance in the Web domain. Through these relations, a graph of browsable information nodes can be built and extended via a REST uniform interface. The node can contain locally stored information, data from external sources, or content dynamically generated upon script-based processing.

We showed how digital representations of sensors, Virtual Sensors and Points of Interest can be designed and published on the Web by leveraging our framework capabilities. We provided users with a set of tools for creating, modifying, and composing these resources, to build a Web of interlinked “smart” objects. Our target users are developers, who are provided with Java and JavaScript libraries for easing server-side and client-side programming, and nonexpert users who are provided with the IDN-Studio and IDN-Viewer plugin for creating, composing, and publishing new Web Resources for their own application needs.

We also discussed the compliance of the current middleware implementation with REST constraints, particularly with HATEOAS.

We presented the results of an experiment carried out within the SmartSantander FP7 EU project for validating the proposed Web of Things framework with qualitative and quantitative evaluations. Users who tested the IDN-Studio and IDN-Viewer tools provided good overall feedbacks. Based on these results, some conclusive reflections have been drawn. First, the Web Resource model has proved to be effective in modeling, handling, and combining smart thing digital representations.

Nodes can be created from scratch with ease and immediately made available by the middleware through IDN-Studio or be generated from external sources (sensors or sensors' gateways) through an adapter component. Owing to the provided programming and Web publishing tools, these Nodes can be managed and further refined, by drawing aggregation and reference links with other Nodes, thus updating the corresponding Web Resource representation served by the middleware.

In the future, we are planning to take into account users' suggestions to improve the ease of use and intuitiveness of IDN-Studio. It will be also worth extending the IDN-Viewer JQuery plugin for supporting additional rendering models. Subsequently, a more comprehensive and in-depth assessment will be performed with a wider user base.

Another direction for future work would comprise the extension of our middleware with adapter components capable of interacting with existing semantic sensor web implementations [20] and the extension of our model to support semantic annotations specifications, e.g., Semantic Annotations for WSDL and XML Schema (SAWSDL) [48] and Semantic Annotations for REST [49]. These extensions are required to enable lifting and lowering mechanisms, opening up our resource graph to advanced reasoning, discovery, and search services.

To conclude, it is worth noticing that our services will be kept running for at least three years after the completion of the SmartSantander project. Thus, programmatic access to the REST APIs and web-based access to the applications for accessing the existing Santander Smart City resources and creating new Smart City applications will be made available upon registration.

ACKNOWLEDGMENT

The authors would like to thank A. Failli and L. Capannesi for their technical support.
